Abstract Trichofolliculoma is a rare follicular hamartoma whose dermoscopic features have been scarcely reported. On the other hand, reflectance confocal microscopy features have not been described yet. In the present study, the authors report reflectance confocal microscopy features in a case of trichofolliculoma as squamous hyperplasia forming irregular finger-like protrusions around the hair follicle and papillomatous hyperplasia of the hair follicle epithelium, which correlated with histopathology. This case suggests that reflectance confocal microscopy may help incorrect in vivo diagnosis of trichofolliculoma in cases difficult to diagnose by morphology and dermoscopy.

Case report

A 66-year-old man was referred to our department because of an asymptomatic slowly growing papule on the chin with 1-year of duration. Physical examination revealed a skin-colored, firm, non-tender papule measuring 4 × 5 mm (Fig. 1A). The dermoscopic picture was non-specific with a whitish-pinkish homogenous structureless area. Prominent follicular openings and linear vessels on erythematous

background were present on both lesional and perilesional sun-damaged skin (Fig. 1B). In Reflectance Confocal Microscopy (RCM) evaluation (Vivascope 3000 Handheld; Mavig GmbH, Munich, Germany), a honeycomb pattern with mild disarray was seen at the epidermal level. There were no atypical cells. There were some bright inflammatory cells. The epidermal thickness was attenuated, and at the Dermoepidermal Junction (DEJ) rings were few and far between. The authors observed squamous hyperplasia forming irregular finger-like protrusions around the hair follicle and papillomatous hyperplasia in the hair follicle epithelium was seen (Figs. 2 and 3). At the dermal level, coarse collagen fibers beneath the follicles were observed. On histopathology, multiple radiate small abortive hair follicles of varying degrees of maturity around a few central dilated primary fol-

icles filled with loose keratin were seen. The abortive hair follicles were secondary or tertiary follicles consistent with the diagnosis of a trichofolliculoma. The stroma between the follicles was cellular, vascularized with some lymphoid cells. Some of the abortive hair follicles located beneath the epidermis. The epidermis was thin and rete ridges were flattened (Fig. 4).

Discussion

Trichofolliculoma is a rare follicular hamartoma mostly seen as a solitary asymptomatic, skin-colored, dome-shaped papule or nodule and usually affects the face and the scalp. The morphologic features of the lesion are generally non-distinctive unless it has a centrally located small tuft of hairs or a central pore.¹ Histopathological appearance is charac-

teristic of one or more primary central dilated follicle(s) and multiple secondary and tertiary hair follicles budding outward centrifugally from the central one.²

Correct clinical diagnosis of solitary non-pigmented lesions may be difficult, and *in vivo* diagnostic techniques have great importance in such cases. Dermoscopy has been widely used for decades in the differential diagnosis of skin lesions, in most of which dermoscopic features have been described in detail. However, dermoscopic features of trichofolliculoma have been reported in only 3 cases until now.^{3–5} In these cases, central brown zone with several radial dark brown projections lying towards the periphery ("firework" pattern), fine peripheral serpiginous vascularization with centripetal disposition, and a white-pink central area with shiny white structures, dotted vessels and a central scale were the reported dermoscopic features. In the present case, a whitish pinkish homogenous structureless

area was the only dermoscopic finding which was not helpful in the diagnosis.

RCM is another *in vivo* technique that has been relatively recently developed. It has advantages with giving cellular details of the upper layers of the skin and can be considered as “optical biopsy” of the living tissue. To the best of our knowledge, there has been no report on RCM features of trichofolliculoma.

In the present case, squamous hyperplasia forming irregular finger-like protrusions around the hair follicle and papillomatous hyperplasia in the hair follicle epithelium was the RCM findings that were concordant with histology. This case suggests that RCM may help incorrect *in vivo* diagnosis of trichofolliculoma in cases difficult to diagnose by morphology and dermoscopy.
