

Allergic contact dermatitis to slime☆☆☆

Dear Editor,

Slime is the colloquial name of a viscoelastic product used as a toy that has gained popularity in recent years among children and adolescents worldwide. It may be home-made or industrialized. The former is obtained by mixing cosmetic and household products, including shaving foams, contact lens solutions containing boric acid, glues, liquid detergents and powdered soap, among others.¹

We report the case of a 9-year-old girl, with personal history of atopy for 5 years with periods of exacerbation related to slime manipulation. The patient's mother informed that she used to play with both: a commercial slime bought at a toy store, and also a home-made one, created by herself using body moisturizer, boricated water, glue, baking soda, blue food dye and shaving foam.

Dermatological examination showed intense palmar erythema, with multiple vesicles associated with desquamation and some exulcerated areas (Fig. 1). Treatment was introduced with 0.5 mg/kg/day systemic corticosteroid therapy and, after 2 months, patch test was performed using the Brazilian standard series, and also complementary aqueous solution of methylisothiazolinone (0.02%) and a part of the industrialized slime (even knowing the possibility of false-positive reactions because of the potential irritants in its composition) (Fig. 2). The 96 h-reading showed positive results for Kathon CG 2+ (a mixture of methylisothiazolinone and methylchlorothiazolinone), and also for isolated methylisothiazolinone (MI) 2+ (Fig. 3), which is a component present in the specific moisturizer, glue and shaving foam used by the patient in manufacturing the homemade slime. The company responsible for manufacturing the industrialized slime was contacted, and they informed that the only preservatives used in its composition were the parabens, which had negative results in the patch test.

Slime can cause both Irritant (ICD) and Allergic Contact Dermatitis (ACD), especially when it is home-made, and so is prepared with the addition of different commercial products. When irritant, boric acid, alcohols and glycol compounds are responsible for the aggression of the skin barrier.² On the other hand, allergens such as methylisothiazolinone and methylchlorothiazolinone are well recognized as causing ACD, and are used as preservatives in industrialized and cosmetic products, such as moist wipes, moisturizers, makeup cleaners glues, among others.³ In the present case, this preservative was present in the body moisturizer, the shaving foam and the glue used by the patient, revealing the importance of identifying the allergens in the numerous products that may be used.

Atopic patients are prone to the development of ACD due to deficiency of the skin barrier and also to frequent use of

skin care products such as body moisturizers containing possible allergens. In the case reported, the patient had hand dermatitis related to atopy, with exacerbation after slime manipulation, resulting in ACD.

In the last year, several reports of ICD and ACD caused by slime were published, what should alert parents and health professionals to the risks of this play, especially when homemade.²

☆☆ Study conducted at the Skin Allergy Sector, Dermatology Clinic, Santa Casa de Misericórdia de São Paulo, São Paulo, SP, Brazil.

Anderson et al.⁴ analyzed the ingredients of 48 slime recipes available on the internet and demonstrated that the most common were fragrance mix I and II, and preservatives such as propylene glycol and MI (the positive allergen in our patient's patch test).⁴

Clinically, the causes of hand dermatitis may be indistinguishable. Patch test is essential, not only for differential diagnosis (ICD and ACD), but also to detect the causative allergen. It is important to identify it, as these substances are also part of patient's everyday products, such as shampoos, soaps and creams. Thus, if there is no precise diagnosis, dermatitis can evolve with relapses, increasing morbidity and making it difficult to control the disease.

Onychomadesis secondary to hand-foot-and-mouth disease: report of two cases^{☆,☆☆}

Dear Editor,

Although onychomadesis secondary to hand-foot-and-mouth disease (HFM) is an uncommon clinical manifestation; it threatens parents and child caregivers. In a case series of 145 Thai patients, it occurred in 5–37% of cases, depending on the virus.¹ HFM is more frequently caused by coxsackie virus, subtype A6, but some enterovirus and echovirus may also be involved. It is common in children below 10 years of

age,² and manifests with flu-like symptoms (fever, lymphadenomegaly, dizziness, vomiting and discomfort) associated to canker sores in the oral mucosae and bullae on the hands and feet. Oral-faecal transmission for 30 after the resolution of symptoms and skin lesions. Nail changes often observed in HFM are Beau lines, leukonychia, and onychomadesis.³ Beau lines are white transverse grooves, resulting from temporary stop in nail plate formation.³ Onychomadesis may be a more severe form of this commitment, when nail growth is interrupted for one or two weeks, resulting in detachment of the nail plate from nail bed. The new nail grows without connection to the older one, leading to splitting and detachment of the older nail. It has been proposed that this alteration may be caused by toxic direct action of the virus in the matrix or by the inflammation secondary to maceration of digital bullae.⁴ According to a case series,¹ onychomadesis is more usual in HFM caused by Coxsackie A6 virus than other viruses. Nevertheless, a Spanish study,⁵ which investigated an onychomadesis outbreak (311 cases) showed high frequency of HFM as a possible cause (60%), a fingering confirmed by identifying coxsackie and enterovirus in faecal
