Received 20 July 2021; accepted 27 August 2021

Case Report

A 76-year-old patient complained an asymptomatic lesion for more than 6 months, consisting of a normochromic plaque on the lower back, somewhat papillomatous with a slightly erythematous center (Fig. 1), with peripheral white striae and microulcerations on dermoscopy (Fig. 2). Histopathological examination showed an epithelial basaloid proliferation with a focially reticulate pattern (Figs. 3 and 4). The excision of the lesion was performed.

What’s your diagnosis?

a) Seborrheic keratosis
b) Fibroepithelioma of Pinkus
c) Superficial basal cell carcinoma
d) Trichoblastoma

Discussion

Fibroepithelioma of Pinkus (FeP) is considered an uncommon type of basal cell carcinoma (BCC), first described by Hermann Pinkus in 1953, who named it a premalignant variant of basal cell epithelioma, and similar to trichoblastomas regarding their degrees of differentiation.1,2 Therefore, some researchers have claimed that both BCC and trichoblastomas can be better classified as opposing representatives of the same spectrum of differentiation, with FeP deserving an intermediate classification within this fine line.1

It is more often reported in females (54%) and the elderly3 and is probably underreported. It presents clinically as normochromic/brown single or multiple lesions, such as papules or plaques, dome-shaped or sessile, which can mimic benign skin lesions that would not be routinely excised or biopsied, such as pedunculated fibroma, acrochordon, seborrheic keratosis, and dermal nevus.4,5 It affects non-photoexposed areas such as the lumbosacral and abdominal region, groin, and foot. On dermoscopy, thin branched vessels, punctiform vessels, white septal striae, corneal pseudocysts, and ulcerations are observed. Some lesions show structureless gray-brown pigmentation and bluish-gray dots.6

Histopathological examination is crucial for the diagnosis as it reveals thin strands of basaloid cells surrounded by stroma, which form a uniform border with the underlying dermis in a fenestrated, honeycomb-like pattern.7,8

Figure 1  Normochromic papillomatous plaque with a slightly erythematous center.

Figure 2  Dermoscopy showing the presence of white striae and microulcerations.

Figure 3  Long, thin, branched and anastomosed epithelial strands of basoid cells originating from the epidermis embedded in a fibrous stroma. (Hematoxylin & eosin, ×100).

Figure 4  Epithelial cell clusters arranged in palisade can be seen along the epithelium, like buds on a branch (Hematoxylin & eosin, ×400).

Treatment consists of the surgical excision of the lesion. The prognosis is good, with low local aggressiveness and low risk for metastasis. 1

Regarding the abovementioned differential diagnoses, seborrheic keratosis is a benign, rounded, or irregular lesion with a brownish or black color, affecting mainly the face and trunk. 2 Superficial basal cell carcinoma more commonly affects the face and neck, presents wide branched vessels on dermoscopy, and is less differentiated on histopathology, not fenestrated. 3 Trichoblastoma is a rarer tumor, with fine arboriform vessels, crown vessels, and pearly white background on dermoscopy, with a fibrocystic stroma, formation of follicular bulbs and papillae on histopathology. 2,4
